

Lublin Spółka z o.o.

Introduction

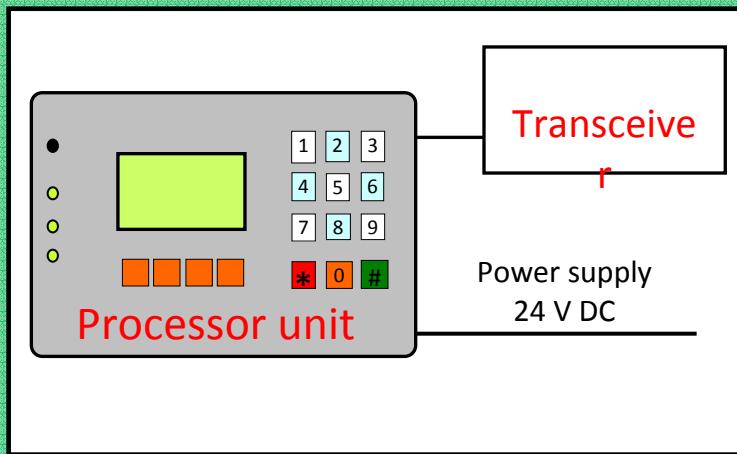

Radio communication is realized through directive antennas on **2.4 GHz** frequency. The communication is realized in a **vertical direction** up or down from the vehicle. Both methods are possible according to the local conditions and customer's requests.

Communication system is characterized by:

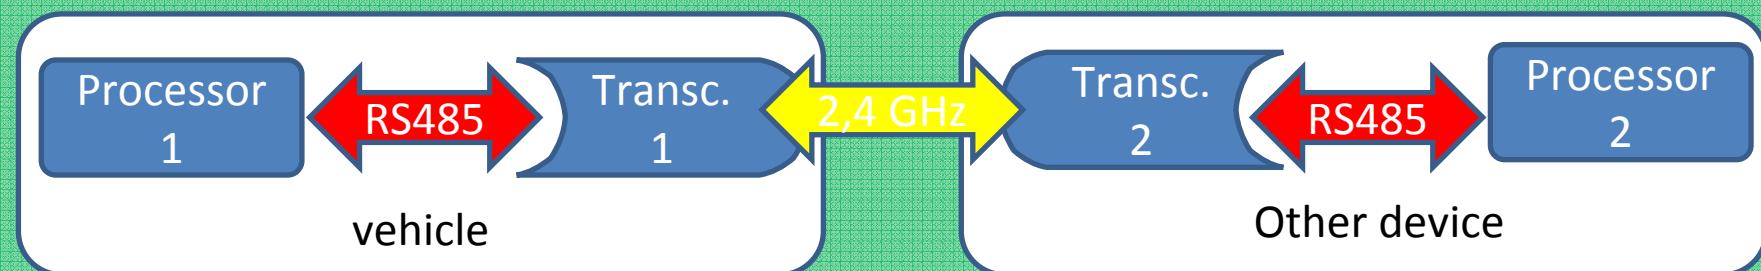

- a high speed transmission of the signal
- a high resistance against disturbance.
- The radio communication system is dedicated for communication between vehicles of municipal transport and devices located on the route.

Description of the ground devices

The ground part is formed by two devices.
the first one is a **transceiver**
the second one is a **processor unit**.

Vehicle permanently transmits a radio signal. The signal contains vehicle identification number, vehicle type, line number, course code and further information according to the client's request.

Vehicle identification number and vehicle type are fixed, adjusted by a service worker. Course is set by the driver. If the terminal is connected to the main board computer, the route setting can be fully automatic.

Typical purposes of usage for high-speed transmission system

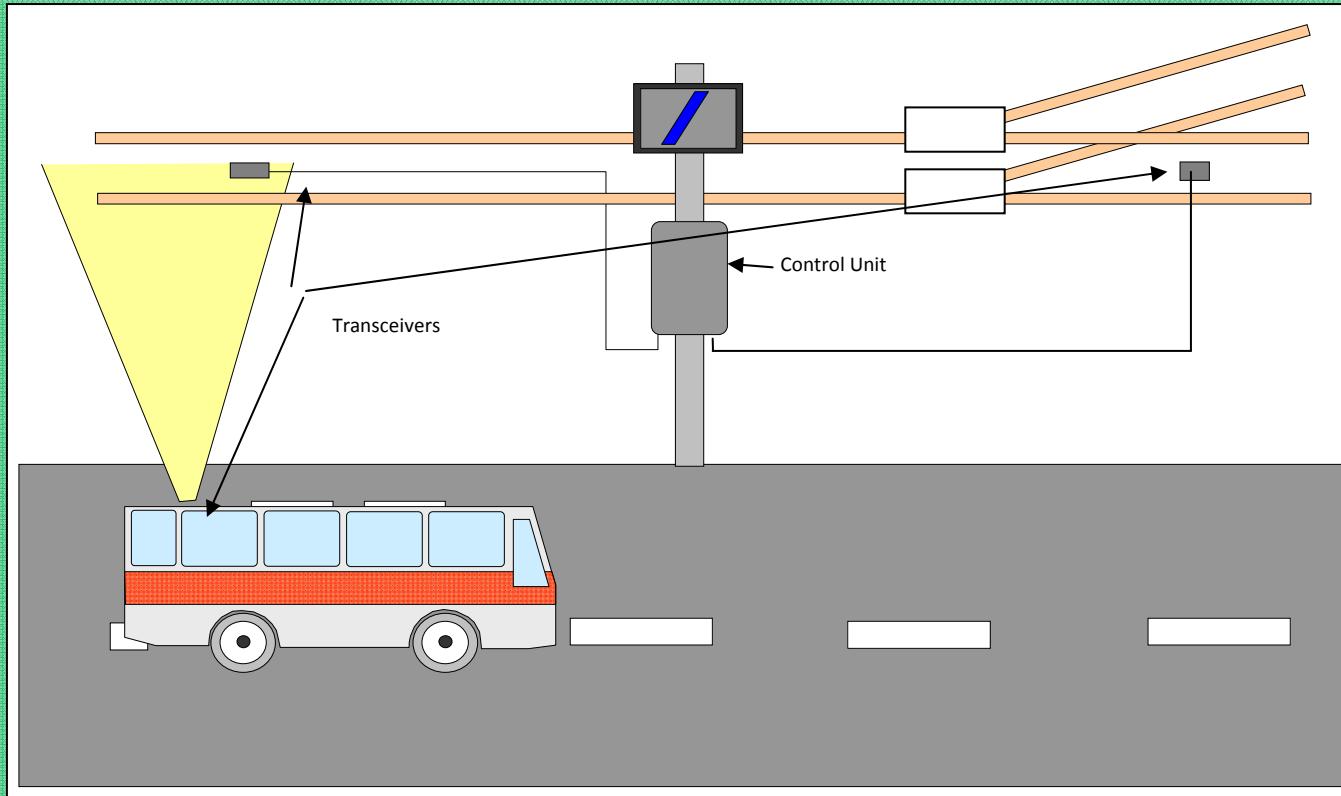

1. Two-way transmission of the signal between a trolleybus and a switch control system; automatic setting of a switch point position and transmission of state or failure announcements.

2. Transmission of the signal from a trolleybus into traffic lights devices; preference of municipal transport vehicles on intersections to other vehicles.
3. Two-way transmission of the signal between trolleybus and vehicle position ground devices ; generates information of the vehicle actual position to the municipal transport dispatching or to the passengers

Tram and trolleybus switch points control system

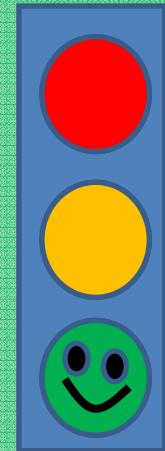

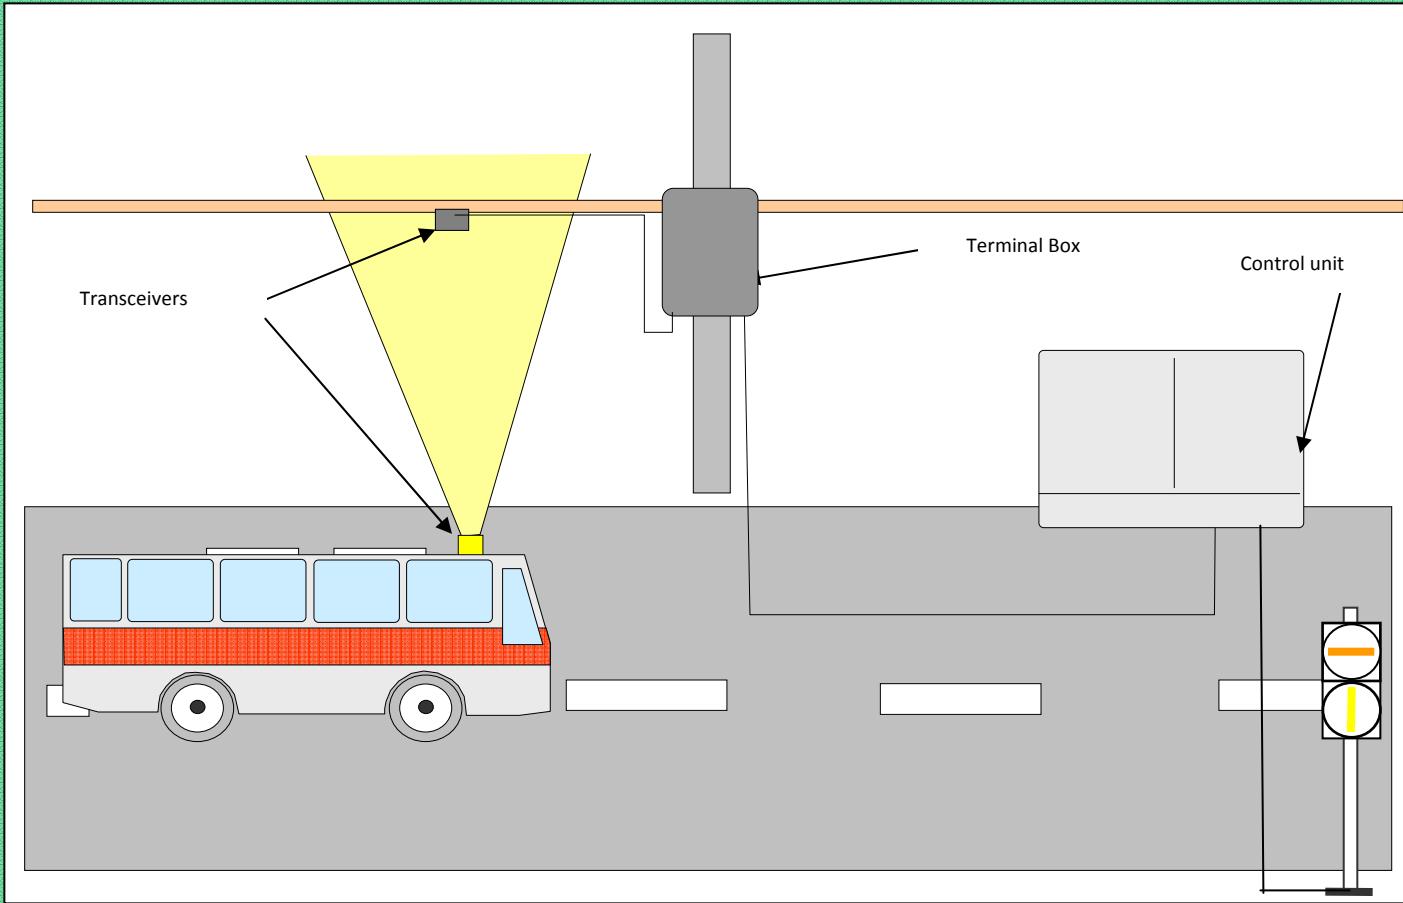

Signal with demand for route setting is transmitted from trolleybus into switch point control systems.

The switch point positioning process is fully automatic..

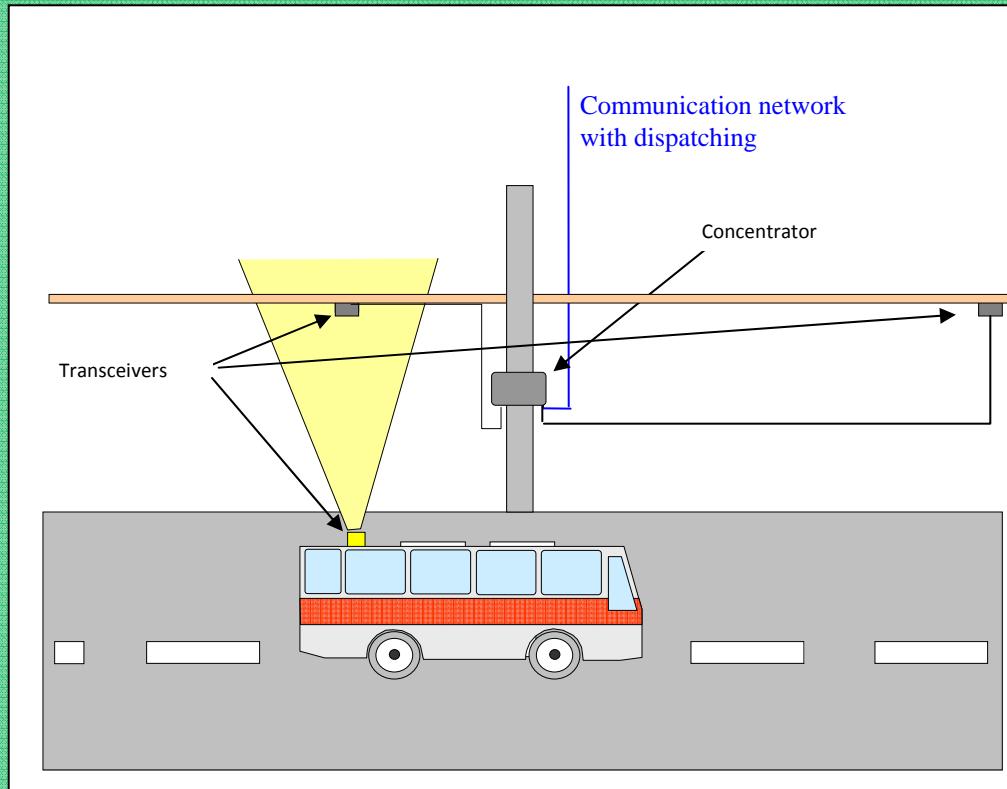

Preference of municipal transport vehicles

Signal with required direction is transmitted from municipal transport vehicles into traffic lights controller which provides preferential passage of these vehicles through intersection.

Vehicle position monitoring system

Signal from vehicles is transmitted into devices of monitoring points on the route.

From these points the signal is transmitted through concentrators and telecommunication cables network (or wireless network) to dispatching and might be used also for a passenger information system

22 Lublin	11.30
23 Prague	16.55

Because each vehicle transmits a unique identification number and course code, computer in dispatching is able to show actual vehicle position; this fact is compared with time table and the computer informs dispatcher about differences.

Description of the vehicle part device

Vehicle **terminal** is possible to connect with a board computer.

Besides signals **transmitted** from vehicles into switch point control systems there would be **transmitted** signals from the switch point control systems into vehicles as well. It would be state or failure announcements.

Transceiver 2,4 GHz

Processor unit - control box

Where drivers prefer automatic control system:

. Into each switch point control system there is downloaded complete sheet of the vehicle courses, **list of switch points** and **relevant directions** on each switch point for each vehicle course. The route is set in accordance with switch point number adjusted in a control system and with a **course code** adjusted on vehicle terminal by the driver. There is also possible to use buttons for direct temporary command for required direction (left or right); this command is superior to the course code.
